

An Unusual AKI

Robert K. Forsythe

March 10, 2021

Abstract

Acute Kidney Injury is one of the most common reasons for hospital admission and are often a side effect of prescribed medications. Acetazolamide is a medication prescribed occasionally for diverse indications including idiopathic intracranial hypertension, glaucoma, prophylaxis of mountain sickness and ventilator alkalosis. Although it is a medication we prescribe relatively often it is not a benign drug and adverse effects include allergic reactions, acidosis and electrolyte derangement. It is a sulphonamide and like other drugs of this class it can cause impaired renal function by a variety of mechanisms including interstitial nephritis, tubular necrosis and crystalluria. Here we describe an unusual AKI caused by acetazolamide.

Introduction

Case

A 72 year old lady attended the emergency department complaining of right sided loin pain for the preceding 36 hours. She had a medical history of hyperparathyroidism, hypothyroidism and a rectocele repaired 6 years ago. Forty-eight hours prior to her attendance she had repair of a macular hole and had been prescribed acetazolamide 250mg twice daily. She had taken 5 doses of this before discontinuing the medication due to nausea, vomiting and loin pain. She then attended A&E. Blood tests on presentation demonstrated reduced renal function with a creatinine of 222umol/L from a baseline of around 70umol/L. Initially she was assessed with a non-contrast CTKUB. This did not demonstrate any nephrolithiasis but did suggest some fullness of the collecting system. Given the CT findings she was further imaged with a renal tract ultrasound which excluded any hydronephrosis.

(b) Ultrasound of left kidney

Unfortunately her renal function continued to decline and a central line was placed and 4 days following admission she was dialysed. Her renal function then made a very rapid recovery and she entered a polyuric phase.

Discussion

A brief review of the literature demonstrated that similar presentations of acute kidney injury have previously been encountered in association with acetazolamide [1, 2, 3]. In each of these cases acetazolamide has been associated with renal colic and anuria. Lawson found that the AKI resolved with aggressive fluid therapy and Neyra's patient required 2 sessions of haemodialysis. Acetazolamide is recognised to be associated with metabolic drug-induced calcium phosphate or oxalate calculi, however in this case these

were excluded by CT imaging. An older case published by Rossert in 1989 describes a similar case in which a biopsy was performed and demonstrated Tamm-Horsfall protein within the glomeruli and tubular lesions associated with intratubular crystal formation. This suggests intratubular obstruction and retrograde flow of tubular urine[2].

Conclusion

When prescribing medications it is important to consider the harms that these medications may cause. Here we describe an unusual but life-threatening side effect of acetazolamide. We must be mindful of recent changes to medications when considering possible aetiology of unusual presentations.
